(Received 15 September 2016; published 1 March 2017)

We experimentally investigate the atom optics kicked particle at quantum resonance using finite duration kicks. Even though the underlying process is quantum interference, it can be well described by an ϵ -pseudoclassical model. The ϵ -pseudoclassical model agrees well with our experiments for a wide range of parameters. We investigate the parameters yielding maximal momentum transfer to the atoms and find that this occurs in the regime where neither the short pulse approximation nor the Bragg condition is valid. Nonetheless, the momentum transferred to the atoms can be predicted using a simple scaling law, which provides a powerful tool for choosing optimal experimental parameters. We demonstrate this in a measurement of the Talbot time (from which h/M can be deduced), in which we coherently split atomic wave functions into superpositions of momentum states that differ by 200 photon recoils. Our work may provide a convenient way to implement large momentum difference beam splitters in atom interferometers.

I. INTRODUCTION AND MOTIVATION

The atom optics δ -kicked particle is a paradigmatic system for experimental studies of quantum chaos and classical-quantum correspondence [1–5]. It consists of laser cooled atoms exposed to a periodically pulsed standing wave (SW) laser field, tuned far off-resonant to relevant atomic transitions. A purely *quantum* phenomenon in such systems is the appearance of quantum resonances (QR) which are a result of self-revivals of the atomic wave function due to the matter-wave Talbot effect [6]. QRs lead to linear (ballistic) growth in the root-mean-square momentum imparted to the atoms with the number of SW pulses [1,7,8]. The nonlinear dynamics of the δ -kicked particle enables measurements with sub-Fourier precision [9] both in the vicinity [10,11] and away from QR [12]. In this context, it is very appealing to realize the large momentum transfer (LMT) of QR as a “beam splitter” (BS) in atom interferometry, as the sensitivity of atom interferometers grows with the momentum difference between the arms. This would allow for applications in high precision metrology such as measurements of the ratio of Planck’s constant to the atomic mass (h/M) [13], etc. A number of atom interferometers today use series of low order Bragg diffraction pulses to realize a LMT BS [14,15]. Using QR bears similarities to this approach since it achieves LMT through consecutive low order diffractions. Compared to a single short pulse BS [6,16], consecutive pulses can yield enhanced momentum transfer to the atoms. Interestingly, the pulse durations we consider are lower by typically two orders of magnitude compared to Bragg pulses [14,15,17]. Using QR thereby reduces the interaction with the SW light, which is a potential source of systematic errors, noise, and decoherence in atom interferometers. Thus, QR is a promising approach for implementing LMT beam splitting processes in an interferometer.

The δ -kicked particle description is valid when the motion of atoms can be neglected during the SW pulses (Raman-Nath approximation). The finite pulse duration often needs

to be accounted for numerically [1,8] when comparing experiments to theoretical predictions. Furthermore, for a given SW power the maximal momentum transfer can be achieved when the SW pulse duration violates the Raman-Nath condition [16,18]. This has motivated the recent development of an ϵ -pseudoclassical model which accounts for the finite pulse duration effects during QR [19]. Here, we provide an experimental test of the ϵ -pseudoclassical model which is capable of predicting the momentum transfer to a group of atoms from finite duration SW pulses. We find that the model agrees well with our experiments for a surprisingly large range of pulse durations. For relevant parameters the width of the momentum distribution can be predicted using a simple scaling law. This is a powerful tool that allows for easy optimization of experimental parameters. We demonstrate this by a measurement of the Talbot time in which we split atoms into coherent superpositions of momentum states that differ by up to 200 photon recoils. For the regime where our LMT BS is realized, neither the Raman-Nath approximation nor the Bragg condition holds.

II. EXPERIMENTAL SEQUENCE

Our experimental sequence is depicted schematically in Fig. 1. We trap a cloud of ^{85}Rb atoms in a magneto-optical trap (MOT); subsequent polarization gradient cooling (PGC) leaves the atoms at $\sim 6.4\ \mu\text{K}$ in the $|5^2S_{1/2}, F=2\rangle$ state. We then apply the SW pulse sequence. The SW field is a laser beam retroreflected by a mirror in the horizontal plane, $\sim 40\ \text{MHz}$ red detuned from the $|5^2S_{1/2}, F=3\rangle \rightarrow |5^2P_{3/2}, F=4\rangle$ transition. For the initial internal state this light is off-resonant with $\sim 3\ \text{GHz}$ red detuning. We apply N SW pulses of duration t_p and period T . After the pulse sequence the atomic cloud freely expands for a 9.9 ms time-of-flight (TOF), and finally we take a fluorescence image of the atomic distribution.

III. THEORY

To account for the finite pulse durations we use the ϵ -pseudoclassical model described in Ref. [19] (conceptually

*mikkel.andersen@otago.ac.nz; <http://www.physics.otago.ac.nz/nx/mikkel/home-page.html>

FIG. 1. Scheme of the experimental sequence. (a) Laser trapping and cooling; SW pulse sequence; expansion of the atomic cloud during time-of-flight; and fluorescence imaging, (b) intensity and detuning Δ of light during the same sequence, not to scale, and (c) fluorescence image.

similar to the approach taken by Wimberger *et al.* [20]). The model is as follows. We consider the one-dimensional atomic motion along the SW axis. If the kicking period T is an integer multiple L of the Talbot time $T_T = 4\pi M/\hbar K^2$ (quantum resonance), then the one period time evolution is governed by the Floquet operator

$$\hat{F} = \exp\left(-\frac{i}{\hbar} \frac{\hat{p}^2}{2M} [LT_T - t_p]\right) \times \exp\left(-\frac{i}{\hbar} \left[\frac{\hat{p}^2}{2M} - \frac{V_d}{2} \cos(K\hat{x})\right] t_p\right). \quad (1)$$

The right exponential term is the time evolution during the SW pulse, and the left the free evolution between pulses. M is the atomic mass, and $K = 2k_L$, with k_L the SW laser wave number. \hat{x} and \hat{p} are position and momentum operators, respectively, and V_d is the SW potential depth.

We rewrite Eq. (1), taking advantage of two properties. First, due to the spatial periodicity of the SW potential the quasimomentum [21] is conserved, so we restrict our analysis to manifolds of a given quasimomentum β [22]. Second, we use the revivals that a spatially periodic wave function undergoes after free space evolution for duration T_T [6]. Equation (1) can be rewritten in terms of rescaled dimensionless quantities $\epsilon = \hbar K^2 t_p / M$, $\hat{\theta} = K\hat{x}$, $\hat{\mathcal{J}} = \hat{p} / \hbar K$ [23], and $\tilde{V} = V_d t_p \epsilon / 2\hbar$ as [19]

$$\hat{F} = \exp\left(-\frac{i}{\epsilon} \left[-\frac{\hat{\mathcal{J}}^2}{2} + \hat{\mathcal{J}} 4\pi L\beta\right]\right) \times \exp\left(-\frac{i}{\epsilon} \left[\frac{\hat{\mathcal{J}}^2}{2} - \tilde{V} \cos(\hat{\theta})\right]\right). \quad (2)$$

In this form of the Floquet operator new quantities appear at different positions. The role of \hbar is played by ϵ which depends on t_p , as also revealed by the commutation relation, $[\hat{\theta}, \hat{\mathcal{J}}] = i\epsilon$. The apparent duration of both exponential operators is one dimensionless time unit. One often speaks of quantum dynamics converging to classical dynamics in the limit of $\hbar \rightarrow 0$. In the ϵ -pseudoclassical model the dynamics of Eq. (2) is approximated with its classical counterpart assuming $\epsilon \ll 1$. The effective classical dynamics is governed by the *effective classical Hamiltonians* extracted from Eq. (2). These are $H_1 = \mathcal{J}^2/2 - \tilde{V} \cos(\theta)$ and $H_2 = -\mathcal{J}^2/2 + \mathcal{J} 4\pi L\beta$. H_1 still has the form of a pendulum, which is exactly solvable in terms of Jacobi elliptic functions. Solving Hamilton's equations of

FIG. 2. Comparison of $\langle \mathcal{J}^2/2 \rangle$ (shown in color coding; see color bars) in different models for $\epsilon = 0.1$, $\tilde{V} = 1$, as described by Eqs. (1) to (3).

motion for H_2 yields the following map, which gives θ_2 and \mathcal{J}_2 after the evolution under H_2 in terms of θ_1 and \mathcal{J}_1 before it:

$$\theta_2 = \theta_1 - \mathcal{J}_1 + 4\pi L\beta, \quad (3a)$$

$$\mathcal{J}_2 = \mathcal{J}_1. \quad (3b)$$

It is important to note that the ϵ -pseudoclassical model is not the classical limit of our physical system. On the contrary, it consists of mapping the system onto a different classical system that captures the quantum dynamics of the actual system. This is illustrated in Fig. 2 where $\langle \mathcal{J}^2/2 \rangle$ (which plays the role of the mean kinetic energy in the ϵ -pseudoclassical model) is plotted as a function of pulse number and initial (quasi-) momentum, computed using different models. For details on the numerical methods, see Appendix A. The ϵ -pseudoclassical model is in quantitative agreement with the full quantum model [Eq. (1)] for the parameters $\epsilon = 0.1$ and $\tilde{V} = 1$ used. Neither the δ -kicked particle model nor the classical model using the Hamiltonians corresponding to the classical limit of Eq. (1) agrees with the full quantum model.

Resonant transfer of kinetic energy to the atoms happens close to $\beta = 0$ and to integer multiples of $1/2$. It leads to a quadratic increase in energy with the number of SW pulses up to a point ($N \approx 5$ pulses in Fig. 2) after which the energy transfer ceases. The strong dependence of QR on β and the limit on the achievable kinetic energy indicates the challenges of transferring large momentum to a finite temperature gas. For instance efficient transfer of momentum to $>95\%$ of the atoms requires an initial momentum width below $0.2\hbar k_L$ for parameters of Fig. 2 and $N = 7$. This can be achieved using a Bose-Einstein condensate or by velocity selection [6,15]. For the quantum δ -kicked particle the quadratic increase in energy is unlimited; however LMT is not feasible due to the increase in required laser power with N . H_1 , H_2 , and Eq. (3) provide insight into the advantage of using consecutive finite duration pulses. For a single pulse the transferred kinetic energy is bounded by the SW potential depth. This can be directly seen from the pendulum Hamiltonian H_1 : when the

FIG. 3. Comparison of experiments and the ϵ -pseudoclassical model. (a) Average of 10 fluorescence images with a logarithmic color map used for calculating momentum distributions. (b) Measured and smoothed momentum distribution without (dash-dotted line) and with a SW pulse sequence (dashed line), and the ϵ -pseudoclassical model for the same parameters (solid line). (c) Difference curves (SW – no SW). The dashed line is measured data, the solid line is from the model, and the dotted line is from the model including a range of potential depths seen by the atoms.

particle reaches the bottom of the potential it will start losing energy by climbing the next hill. Considering the $\beta = 0$ subspace and Eq. (3) we see that the evolution governed by H_2 does not change the scaled momentum \mathcal{J} (and therefore not the actual momentum) but it changes the position in the opposite direction to the momentum. This means that after the particle has rolled down a hill, picking up kinetic energy, the free space evolution by H_2 may bring it back up the hill, thereby allowing it to roll down the hill again during the next evolution under H_1 , permitting it to pick up more energy and momentum. This way the particle can gain significant energy by rolling down the same hill many times. The origin of this apparent backwards motion is in the matter-wave Talbot effect. We note that the free space evolution in Eq. (1) is for a duration $LT_T - t_p$. Since a spatially periodic wave function revives every T_T , evolving for a duration $T_T - t_p$ is equivalent to a free space evolution of t_p backwards in time. In the ϵ -pseudoclassical model this translates to the position changing in the opposite direction of the momentum. Note, that if $\beta \neq 0$, we get additional motion during the free flight ($4\pi L\beta$ term) suppressing the resonance effect.

IV. RESULTS

A. Validation of the ϵ -pseudoclassical model

To compare measurements with the ϵ -pseudoclassical model, we investigate the cross-sectional atomic distributions along the SW beam axis obtained from averaging ten repetitions of the experimental sequence (see Fig. 3). The cross-sectional distributions in the case of no SW light and of a sequence of $N = 6$ pulses are plotted (dash-dotted and dashed lines, respectively) for parameters $t_p = 250$ ns, $V_d/h = 7.24$ MHz, and $L = 1$. The total time in the two cases was the same. We deduce the momentum, in units of photon recoil momentum ($P_r = \hbar k_L$), from the images using

FIG. 4. ΔP_{\max} dependence on t_p . Measured data (circles), the quantum δ -kicked particle model (squares with linear fit), the full quantum model (triangles), and the ϵ -pseudoclassical model (thick solid line) for the same parameters.

the time-of-flight. The atomic distributions are broadened due to the SW kicks and a fraction of atoms undergo LMT. To observe the distribution at the wings more carefully, we subtract the distribution with no SW pulses. This difference is shown in Fig. 3(c) in a logarithmic scale after smoothing (dashed line); see Appendix B. We determine the maximum momentum difference of the atomic distribution, ΔP_{\max} , at a universal threshold value, indicated with the horizontal dashed line in Fig. 3(c). The threshold value is chosen to be above the measurement noise level, and it is a fixed value for all measurements. Solid lines in Fig. 3 are calculations with the ϵ -pseudoclassical model. For these calculations the initial width of the atomic distribution and V_d were chosen as best fit parameters, and they are within 25% of the estimated value determined using measured quantities (see Appendices C and D for the experimental parameters).

The ϵ -pseudoclassical model proved to be a great tool to understand various effects that may come into play during the LMT process. Due to the flexibility of the Monte-Carlo simulations, we could easily include various effects that imitate possible physical processes that atoms undergo during their interaction with the SW light sequence without a significant increase in the computational time. Such effects are phase fluctuations of the SW field or spontaneous photon scattering resulting in incoherent momentum exchange. We also modeled the effect of nonuniform potential depth over the atomic cloud, which we found to be the dominant effect for the small deviation observed in the upper part of the shoulders in Fig. 3(c) (see Appendix D for details). Including these variations yielded only a small difference in ΔP_{\max} ; therefore we omit them in the following.

In Fig. 4 we compare ΔP_{\max} values calculated with the ϵ -pseudoclassical model, the full quantum model, and the δ -kicked particle model to experimental data. We plot ΔP_{\max} values for a series of pulse durations t_p , with $V_d/h = 7.24$ MHz and $N = 6$. The experimental data (circles) are in good agreement with the ϵ -pseudoclassical (thick solid line) and full quantum models (triangles). Here, the range up to $\epsilon \approx 0.39$ ($t_p = 2 \mu\text{s}$) is shown, but the agreement holds up to $\epsilon \approx 1$. This is surprising, as $\epsilon \ll 1$ was assumed for the ϵ -pseudoclassical model to be valid. In contrast, the δ -kicked particle model (squares with linear fit) that predicts linear growth deviates significantly for $t_p > 250$ ns. We note that,

FIG. 5. Scaling law. The lines show calculations from the ϵ -pseudoclassical model with t_p scanned at $N = 6, V_d/h = 7.24$ MHz (solid line), $N = 9, V_d/h = 6.64$ MHz (dashed line), $N = 10, V_d/h = 3.47$ MHz (dotted line), and $N = 14, V_d/h = 2.57$ MHz (dash-dotted line). Triangles show measured data within the range of $N = 5$ to 12 and $V_d/h = 2.26$ to 7.24 MHz. The inset shows the scaling law for $\langle \mathcal{J}^2/2 \rangle$ with $N = 10, 50, 100$, and $V_d/h = 18.5, 3.7, 0.62$ MHz, respectively, for $\beta = 0$.

when a combination of parameters is large (typically when both $t_p > 2 \mu\text{s}$, $V_d/h > 7$ MHz, and $N > 12$), we observed significant discrepancies between the experimental data and the models. This could be due to phase instability of the SW.

B. Scaling law

For the $\beta = 0$ subspace, [19] found that $\langle \mathcal{J}^2/2 \rangle$ followed a universal curve if the horizontal axis was scaled appropriately. The general form of this scaling law includes variations in V_d as shown in the inset of Fig. 5. We wish to verify this scaling law experimentally. Since we use a thermal gas, a measurement of the mean kinetic energy or $\langle \mathcal{J}^2/2 \rangle$ would be skewed by the large proportion of atoms with β away from resonances. However, for a wide range of parameters, ΔP_{\max} is dominated by the resonant atoms, so it is intriguing to investigate if an equivalent scaling law exists for ΔP_{\max} . Figure 5 shows an equivalent scaled graph for ΔP_{\max} assuming that $\langle \mathcal{J}^2/2 \rangle$ of the $\beta = 0$ subspace is proportional to ΔP_{\max}^2 . The scaling law is transformed (see Appendix E for details) to make the vertical axis independent of t_p , such that we can use Fig. 5 to determine the optimal value of t_p . We find that, for the parameters chosen, ϵ -pseudoclassical calculations and experimental data approximately follow a universal curve. If one chooses parameters such that ΔP_{\max} is not determined by the resonant atoms (e.g., when the characteristic shoulder in Fig. 3 is below our threshold line), then we naturally see deviations from the universal curve.

C. Measurement of the Talbot time

The scaling law described above provides a powerful tool for choosing optimal parameters for experiments using QR. To illustrate this we carry out experiments to observe resonant momentum transfer to atoms as T is scanned across T_T . For chosen values of $N = 10$ and $V_d/h = 5.89$ MHz, the scaling law predicts that the largest ΔP_{\max} on resonance is achieved for $t_p \sim 430$ ns. Figure 6 shows measured data with these parameters. For comparison, data at other values of t_p are also plotted (180 and 650 ns). We see that the largest

FIG. 6. Measurements of the Talbot time. Optimum performance is at $t_p = 430$ ns (circles and dash-dotted line as a guide for the eye). Squares and triangles were measured at $t_p = 180$ and 650 ns, respectively.

momentum transfer as well as highest (relative to its baseline) and narrowest peak occur at $t_p = 430$ ns, as expected. From a measured Talbot time ($T_T = 64.8 \mu\text{s}$), one can deduce h/M , where h is Planck's constant. High precision determination of h/M is of general interest, as together with other well known constants, it constitutes a measurement of the fine structure constant [13].

V. DISCUSSION AND CONCLUSION

The maximum momentum difference of the atomic distribution measured at resonance in Fig. 6 is $\Delta P_{\max} = 202\hbar k_L$. If one uses QR as a BS in an atom interferometer, then ΔP_{\max} measures the momentum difference between the interferometer arms. In comparison, the state-of-the-art schemes of a LMT BS are typically reaching lower values [14,24,25]. It has to be noted that the measurement in Fig. 6 can be interpreted as an atom interferometer itself since QR is a matter-wave interference effect. We would like to point out that we use short pulses compared to Bragg diffraction schemes, which is beneficial for avoiding incoherent photon scattering events. On the other hand, we use pulse durations above the validity range of the δ -kicked particle approximation. Interestingly [17] found that when operated in the quasi-Bragg regime (using t_p too short to fulfill the Bragg condition), their Bragg based atom interferometer reached the highest contrast for T that gives rise to QR.

To conclude, we have shown that with just 10 pulses we can generate momentum differences of around $200\hbar k_L$. Using QR with finite duration pulses is therefore a promising scheme for a LMT BS that may be applicable in high precision metrology. Furthermore, we have experimentally verified an ϵ -pseudoclassical model that includes finite pulse duration for the atom optics kicked particle at QR. This model captures the quantum behavior with an effective classical treatment. We have found a practically useful scaling law to predict the momentum separation generated as a function of experimental parameters. Combined with the ϵ -pseudoclassical model, this is a powerful tool to choose optimum parameters for atom interferometry based on QR.

APPENDIX A: NUMERICAL METHODS

For the full quantum model the Floquet operator \hat{F} [Eq. (1)] is applied N times (number of SW pulses) to a momentum eigenstate. For a thermal atomic distribution we first calculate the momentum space wave function using the Floquet operator for a range of initial momenta spanning from -160 to 160 photon recoil momenta. Then we average the momentum space probability densities, each weighted with the probability for the initial momentum found from a Maxwell-Boltzmann distribution with the experimentally measured temperature. This yields the momentum distribution that is used to determine the spatial distribution from an initial point source after the time-of-flight. This is convolved with the initial spatial distribution of the atomic cloud to get the final atomic distribution. The momentum distribution in Fig. 3 is obtained by converting the spatial coordinate x to momentum by $p = xM/t_{\text{TOF}}$, where M is the atomic mass and t_{TOF} is the time-of-flight.

For the δ -kicked particle the \hat{F} operator was simplified by the following. (i) The $\hat{p}^2/2M$ term is neglected during the interaction with the SW pulses and (ii) the free evolution term is applied for a time LT_T instead of $LT_T - t_p$. The distribution of the atomic cloud is calculated following the same steps as for the full quantum model.

In the ϵ -pseudoclassical model [19] we averaged the outcomes for a large number of atomic trajectories (typically 10^5) with initial conditions randomly sampled from the initial momentum and position distributions. For all subfigures of Fig. 2 we used an initial momentum of $\beta\hbar K$, and for the classical and the ϵ -pseudoclassical models a flat distribution of position over the spatial period of the SW.

APPENDIX B: DATA ANALYSIS

To determine the maximal momentum width we applied smoothing to the measured momentum distribution in order to suppress noise fluctuations in the regions without atoms. This was done using a moving average filter with a span of $4\hbar k_L$, using Matlab's default smoothing function five times.

APPENDIX C: INITIAL ATOMIC DISTRIBUTIONS

The initial momentum distribution was determined from the time-of-flight measurements. The initial position distribution was estimated from a reverse extrapolation of time-of-flight measurements. The width of this distribution varied up to 20% over the measurements.

APPENDIX D: DIPOLE POTENTIAL DEPTH

1. Calculation of the dipole potential depth

The potential depth V_d is determined from the light shift (AC Stark shift) on the ground state of the atoms caused by the ~ 3 GHz red-detuned linearly polarized standing wave (SW) light beam. In our experiments the ^{85}Rb atoms are prepared in the $F = 2$ ground state and the SW light is 40

MHz red detuned from the $F = 3$ to $F' = 4$ transition. Due to the close vicinity of the D_2 line we only include transitions on this line in the calculation of the light shift. Using the dipole matrix elements $\mu_{m_F j}$ between the ground state ($F = 2$) and the multiple excited states ($F' = 1, 2, 3$) and the detuning values $\Delta_{m_F j}$, the dipole potential can be expressed as follows [26]:

$$U_{m_F} = \frac{I_0}{2\epsilon_0 c \hbar} \sum_j \mu_{m_F j}^2 / \Delta_{m_F j}. \quad (\text{D1})$$

I_0 is the light intensity, ϵ_0 is the vacuum permittivity, and c is the speed of light in a vacuum. Since we are using linearly polarized light and a relatively large detuning, the variation of U with m_F is less than 1% and is neglected.

To estimate the potential depth, we need to determine the light intensity in the SW beam. For this we measured the incoming beam power, beam waist, and losses on the relevant optical elements. V_d is the difference between the dipole potential value at the peak intensity (in the SW antinodes) and its value at the minimum intensity (in the SW nodes). The minimum intensity is not zero due to the power mismatch between the incoming and the retroreflected beams creating the SW beam.

2. Variation of the dipole potential depth

We have observed several effects that may cause different atoms experience different dipole potential depths. The main contribution arises from the spatial variation in the intensity of the SW beams. We have measured that the beams contain an intensity variation of up to a factor of 2 difference between minimum and maximum values over the region that the atoms occupy. Furthermore, we observed SW power fluctuations of up to 10% over the experimental runs. We ascribe the variation of V_d required for best fit to the measurement shown in Fig. 3(c) to these imperfections.

APPENDIX E: THE SCALING LAW FOR A FINITE TEMPERATURE GAS

Our aim is to find and experimentally verify a scaling law that helps to optimize the experimental parameters for large momentum transfer. The free parameters are N , V_d , and t_p . N and V_d are typically constrained; their ideal choice is thus straightforward (for example for V_d the optimal choice is to use the maximal laser power available). The optimal value for t_p is nontrivial. We therefore wish to use the scaling law to determine it. To do so, we need to modify the scaling law, i.e., the $\langle \mathcal{J}^2/2 \rangle$ versus $N\tilde{V}$ function (shown as the inset of Fig. 5), such that the vertical axis contains ΔP_{max} but is independent of t_p (see definitions of \mathcal{J} , N , ϵ , and \tilde{V} in the main text.) Since we use a thermal gas, a measurement of the mean kinetic energy or $\langle \mathcal{J}^2/2 \rangle$ would be skewed by the large proportion of atoms with β away from resonances. For a wide range of parameters, ΔP_{max} (which was introduced to be the maximal width of the momentum distribution) is dominated by the resonant atoms, so it is a good choice to search for an equivalent scaling law expressed in terms of ΔP_{max} . We assume that $\Delta \mathcal{J}_{\text{max}} \equiv \Delta P_{\text{max}} K t_p / M$ is proportional to $\sqrt{\langle \mathcal{J}^2/2 \rangle}$ (for the

$\beta = 0$ subspace). This is naturally also a universal function of $N\tilde{V}$, but $\Delta\mathcal{J}_{\max}$ contains t_p . The vertical axis of the universal curve can be multiplied or divided by any function of the horizontal scale, while still remaining a universal curve. To find a scaling law with the vertical axis independent of t_p , we divide $\Delta\mathcal{J}_{\max}$ by $\sqrt{N\tilde{V}} = Kt_p\sqrt{NV_d/2M}$. In this way the value of t_p that maximizes ΔP_{\max} for any given V_d and N can be determined from the peak of the graph.

Figure 5 shows the experimentally motivated scaling law. The vertical axis is proportional to ΔP_{\max} , and it is given in units of the square root of time. For our choice of units we have omitted a constant $\sqrt{2/M}$ and divided the expression for $\Delta\mathcal{J}_{\max}$ by $P_r/\sqrt{\hbar}$, such that ΔP_{\max} is in units of P_r and V_d is in units of frequency. This expression is independent of t_p . Thus, we can use Fig. 5 to determine the optimal value of t_p for given V_d and N .
